ABSTRACT

Vitamin D has been shown to be beneficial at reducing the risk of cancer; however, studies examining esophageal and gastric cancer have been scarce and findings inconsistent. The UK Biobank cohort was used for this nested case–control study (N = 3732). Primary, incident esophageal and gastric cancer cases diagnosed after recruitment were identified via linkage to National Cancer Registries. Tropospheric Emissions Monitoring Internet Service database was used to calculate ambient annual UVB dose (D-UVB). Conditional logistic regression was used to investigate the relationship between annual ambient D-UVB and risk of esophageal and gastric cancer, and odds ratios (ORs) are reported. In total, 373 esophageal and 249 gastric cancer cases and 3110 age- and gender-matched controls were included in the study. We found a strong inverse association between annual ambient D-UVB and odds of developing esophageal or gastric cancer: Compared to the lowest tertile, OR for the highest tertile was 0.64 (95%CI:0.51–0.79) in adjusted analysis. The association was strengthened when restricted to esophageal cancer (OR = 0.60; 95%CI:0.45–0.80) and esophageal adenocarcinoma cases (OR = 0.48; 95%CI: 0.34–0.68). Similar results were found in unadjusted and stratified analysis. In conclusion, ambient UVB radiation is inversely associated with the development of esophageal and gastric cancer, even in a high-latitude country.

INTRODUCTION

An estimated 456 000 new cases and 400 000 deaths in 2012 make esophageal cancer the eighth most common cancer worldwide, but the sixth most common cause of cancer death due to a very poor survival (1). Similarly, gastric cancer is the fifth most common malignancy, but the third leading cause of cancer death worldwide (951 000 new cases and 723 000 deaths) (1). Two main histological subtypes of esophageal cancers are adenocarcinoma and squamous cell carcinoma (SCC). Notably, the two subtypes differ in terms of their risk factors and incidence patterns (2–4). The majority of adenocarcinoma cases develop from Barrett's mucosa in the lower third of the esophagus, while SCC typically occurs in the upper two-thirds of the esophagus (3).

Synthesis of vitamin D in the skin following exposure to UVB from sunlight is the main source of vitamin D for humans, particularly among those who do not take vitamin D supplements (5). Vitamin D has been associated with reduced risk of multiple internal cancers (6–8). For esophageal and gastric cancer, the evidence is sparse and vastly mixed: a recent systematic review (9) found an increased risk of esophageal cancer overall with higher 25-hydroxyvitamin D [25(OH)D] concentration; a nonsignificantly increased risk of adenocarcinoma with higher dietary vitamin D intake, but a nonsignificantly decreased risk of SCC (10–12). Finally, a single study reported a significantly decreased risk of adenocarcinoma with higher lifetime UVB exposure (13). In a similar study, a nonsignificantly decreased risk of gastric cancer was observed with higher 25(OH)D, but a nonsignificantly increased risk with higher vitamin D intake (14). Therefore, mixed evidence from a limited number of mostly small studies prevents any conclusions from being drawn and highlights the need for more research (14,15). Additionally, dietary sources of vitamin D from food have been shown to be poor determinants of vitamin D in some studies (8,16), and therefore, the results from studies measuring only dietary sources from foods should be interpreted with caution. 25(OH)D is known as the best measure of vitamin D status at a given point in time; however, it is strongly affected by the season of blood draw and other, sometimes particular circumstances (e.g. return from sun holiday); moreover, it does not capture exposure over a prolonged time period. This may be important when examining the relationship between 25(OH)D and conditions which take time to develop. Furthermore, 25(OH)D concentration at the time of blood draw may be of limited relevance: For example, vitamin D status at cancer diagnosis is of limited value when assessing the role in cancer occurrence. Therefore, using UVB instead of 25 (OH)D offers some important advantages for epidemiological studies, provided it can be captured accurately—but this has largely not been the case to date, as most studies use total UV dose, ignore important factors such as cloud cover and ozone or assume equal exposure for the large geographical region; in addition, majority of published studies that used UV are ecological in design.

In this study, we seek to examine the association between the annual ambient UVB at the place of residence and esophageal and gastric cancer occurrence in a large, nested prospective case–control study. The UVB measure we used improves upon variables used previously in multiple dimensions and offers the

most accurate estimate of ambient, vitamin D–synthesizing UVB dose to date.

METHODS

Study participants. Data from the UK Biobank cohort of 500 000 community-dwelling individuals (aged 40–70 years) recruited across England, Scotland and Wales between 2006 and 2010 were used (17). Ethical approval was obtained, and all participants gave informed consent (18). This project was conducted under application number 12653. A subset for this cohort with information on residential location was selected for this study (n = 466 206).

Participants filled in a number of questionnaires, providing information on sociodemographic characteristics and lifestyle, including the following: age, gender, residential location, education [a number was assigned in a hierarchical fashion; 1: none of the above, 2: Certificate of Secondary Education or ordinary-level general certificate of education, 3: advanced-level general certificate of education, 4: National Vocational Qualification or Higher National Diploma/Certificate, 5: other professional qualifications, 6: college or university degree], smoking, alcohol use, vitamin D supplement use [derived from reported use of supplements], diet [frequency of consumption of different foods, including oily fish], physical activity levels in the last 4 weeks [none; low: walking for pleasure (not as a means of transport) and light DIY (e.g. pruning, watering the lawn); medium: heavy DIY (e.g. weeding, lawn mowing, carpentry, digging) and other exercises (e.g. swimming, cycling, keep fit, bowling); high: strenuous sports], ease of tanning, use of sun protection, and time spent outdoors (average number of hours/day in summer and winter; the average of these was calculated and categorized: 0–2 h day^{-1} represented "low" category, 2–5 h day^{-1} represented "intermediate," and >5 h day^{-1} represented "high" level of time spent outdoors).

Information about participants' health was collected. Self-reported presence of different esophageal or gastric problems was identified (including gastro-esophageal reflux, Barrett's esophagus or gastric ulcers), and information on other conditions, such as osteoporosis, cardiovascular conditions and diabetes, was also collected. Participant's height and weight were taken and used to calculate BMI. More detail about the cohort can be found elsewhere (17,19,20).

Case–control cohort. Information on cancer diagnosis after recruitment to UK Biobank was gathered via linkage to the national cancer registries, which register and collect data on all cancers diagnosed. This provided detailed information on cancer characteristics including tumor histological information (esophageal SCC or adenocarcinoma) and ICD-10-CM diagnosis codes—these were used to identify esophageal and gastric cancer cases and obtain exact location of esophageal cancer: C15.3/15.4 denoted upper and middle thirds of the esophagus (typical location for SCC) and C15.5 denoted lower third (typical location for adenocarcinoma) (21).

Flowchart of participant selection is outlined in Fig. 1. In total, there were 416 936 participants with no cancer diagnosis at the time of recruitment. There were 622 incident esophageal and gastric cancer cases diagnosed after recruitment, and these were kept in our study. Eligible controls were selected from the pool of individuals (n = 396 306) who had never had a diagnosis of cancer (including skin cancer), either self-reported (N = 7213) and not on the national registry or registered in the national cancer registry (N = 42 057). All individuals in the cohort who matched in gender and ±one year of age for a given case were identified, and five were randomly chosen from that set for a given case, as age- and gender-matched controls. Controls could not be matched to cases based on their recruitment date as recruitment was linked to location; as a consequence, unwanted matching by UVB would occur.

UVB data source and annual ambient D-UVB. UV dose data from the Tropospheric Emission Monitoring Internet Service (TEMIS) database (www.temis.nl/uvradiation/UVdose.html; version 2.0) were used (22). This service, provided by the Royal Netherlands Meteorological Institute in conjunction with the European Space Agency, determines the amount of UV radiation incident at the surface of earth in Wm^{-2}, as a function of the total ozone column (derived from satellite observations) and the solar zenith angle at a given local solar time (22). As the potential to induce vitamin D synthesis varies dramatically with wavelength, only UVB radiation restricted specifically to wavelengths which can induce cutaneous vitamin D production was considered (290–315 nm) and a weighting function was applied (peak synthesis occurs at 295–298 nm) (23). Moreover, a correction for cloud cover, surface elevation and surface UV reflectivity (UV albedo) is applied to the estimate. We denote this as D-UVB (further detail can be found elsewhere (15,22)). The data are provided on a 0.25°×0.25° (longitude × latitude) grid with each grid cell covering an area of approximately 28 km (north–south) × 17 km (east–west); 782 such grid cells cover Scotland, England and Wales.

Each participant was assigned a TEMIS grid cell based on their residential location. We calculated the annual ambient D-UVB dose for each participant by summing up daily doses, for the year (365 days) preceding the date of recruitment to UK Biobank. Median and interquartile range (IQR) were reported. The annual ambient D-UVB at a given location does not change dramatically from year to year; hence, the annual D-UVB dose in a 1-year period is predictive of the annual D-UVB dose for another 1-year period (Figure S1). As D-UVB is seasonal, it is important to include D-UVB doses for an entire year to prevent seasonal bias in the estimate leading to misclassification of D-UVB dose received by individuals. An example of D-UVB dose's over one location (London) is shown in Figure S1.

Statistical analysis. Conditional logistic regression was used for primary analysis of an association between annual D-UVB dose and odds of developing esophageal or gastric cancer. Each case was assigned a specific five controls for this, so when stratified by cancer type/cancer location, the controls were stratified according to their specific case's cancer diagnosis. Odds ratios and confidence intervals were calculated based on annual D-UVB tertiles (lowest as reference). P for trend was also determined using annual D-UVB as a continuous variable. Covariates used in the final model were smoking status, alcohol intake, BMI, qualifications, gastro-esophageal reflux and gastric ulcers. Backward stepwise regression was used to determine the final model, and model was selected by balancing the lower numbers of AIC/BIC scores, along with a high r^2 number and a low number of missing samples. Other covariates were also considered, but excluded in final model (ease of tanning, use of sun protection, average sun exposure, skin color, oily fish consumption, average time spent outdoors, egg consumption, vitamin D supplementation, osteoporosis, cardiovascular condition and diabetes). The 10% rule was also used to determine confounders; however, there was little difference observed between the two methods and the final method chosen was backward stepwise regression. Conditional logistic regression based on quintiles of annual D-UVB and unconditional logistic regression using tertiles of annual D-UVB were also carried out and are shown in Tables S1 and S2.

Stratified analysis by gender, BMI, age, cancer type, esophageal cancer subtype (gastric cancer subtype was unavailable to us), cancer location, alcohol consumption, smoking status, time spent outdoors over summer and winter months, sun protection used, oily fish consumption, skin color, physical activity and supplement use was also carried out. In accordance with Abnet *et al.* (10), unconditional logistic regression was used in stratified analysis. All analyses were performed in R (R Development Core Team, 2011) and using the R-package "Survival" (Thomas Lumley, 2015). $P < 0.05$ was considered statistically significant.

RESULTS

In total, 3732 participants (622 cases and 3110 controls) were included. Median age of the cohort was 63 years (interquartiles range, IQR: 59–66 years) and nearly three-quarters (74%) were male. Cases and controls were similar in terms of baseline characteristics, although there were a higher proportion of those with Barrett's esophagus (2.1% *vs* 0.4%) and gastric/esophageal reflux (7% *vs* 5%) and those who are previous or current smokers (66% *vs* 52%) among cases (Table 1). Median time from attendance to cancer diagnosis was 3.09 years.

The majority of participants (78%) reported fair or very fair skin tone. A minority (3%) used vitamin D supplements, but 58% reported consuming oily fish more than once a week. There was little difference between cases and controls with oily fish consumption, supplement use and time spent outdoors, on average or during the summer. A general trend toward lower annual D-UVB doses as the latitude increases was observed (Fig. 2A). Median annual ambient D-UVB among controls was 749 kJ m^{-2}

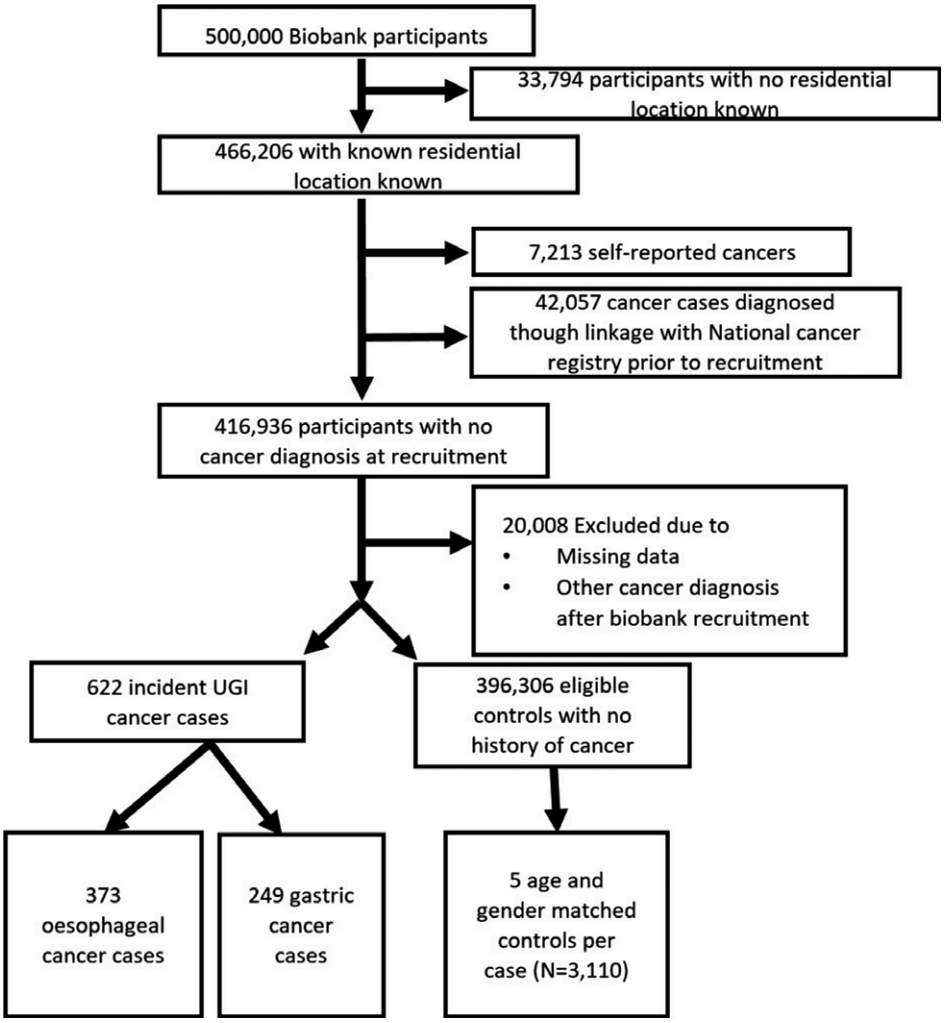

Figure 1. Flowchart of case and control selection from UK Biobank cohort. This figure demonstrates how we extracted the relevant incident cases and controls for the study. Controls had no previous history of cancer and no cancer diagnosis (including nonmelanoma skin cancer) at follow-up. Cases were matched to controls in a 1:5 ratio. Controls were matched in two ways, by gender and ±1 year age, and then further matched on smoking status, alcohol consumption and BMI.

(IQR: 708–817 kJ m^{-2}), and it was lower among cases (741 kJ m^{-2}, IQR: 690–803 kJ m^{-2}; Fig. 2B).

A significant inverse association was found between annual D-UVB and any primary upper gastrointestinal cancer, in unadjusted (OR = 0.60, 95%CI: 0.49–0.75) and adjusted analysis (OR = 0.64, 95%CI: 0.51–0.79), when comparing highest to lowest tertile (Table 2). Stratification by cancer location revealed a 40% decreased odds of developing esophageal cancer (OR = 0.60, 95%CI: 0.45–0.80) and 32% reduction in gastric cancer (OR = 0.68, 95%CI: 0.48–0.96). The association was further strengthened when restricted to cancer of the lower third of the esophagus (OR = 0.47, 95%CI: 0.32–0.70), and adenocarcinoma, the histological type typical for this location (OR = 0.48, 95%CI: 0.34–0.68). Near-identical results were found with unconditional logistic regression (Table S1). In addition, higher D-UVB dose was found to be associated with decreased risk of esophageal and gastric cancer in stratified analysis (Table 3).

Greater risk reduction was observed when comparing Tertile 3 to Tertile 1 than Tertile 2 to Tertile 1. For example, a risk of adenocarcinoma was reduced by 33% in Tertile 2, but by 36% in Tertile 3. This demonstrates that higher UVB has a greater effect on risk. Similar results were also found when annual D-UVB was split by quintiles, with decreasing odds of upper gastrointestinal cancer incidence with increasing quintile: For quintiles 2–5 *vs* quintile 1, ORs were 0.66, 0.59, 0.59 and 0.52. Similar trend was also observed for when restricted by cancer type and subtype (Table S2).

DISCUSSION

In this large, prospective, nested case–control study, a strong protective effect of higher annual vitamin D–inducing UVB dose at a place of residence on upper gastrointestinal cancer risk was observed: A 42% reduction in esophageal cancer and a 32% reduction in gastric cancer risk were found when comparing the highest tertile of UVB with the lowest. This relationship was particularly clear for esophageal adenocarcinoma, where risk reduction of 52% was noted for those in the highest tertile of annual D-UVB. This inverse relationship persisted after adjustment for a range of potential confounders (including smoking,

alcohol, BMI, and different esophageal or gastric problems), and in stratified analysis.

As UVB is one of the main sources of vitamin D in humans, the results in this study not only add important clarity to the relationship between UVB and upper gastrointestinal cancer risk, but they also have important implications for the relationship between vitamin D and cancer outcomes. Evidence of a protective effect vitamin D may have on cancer occurrence is accumulating in the literature, although findings from randomized clinical trials (RCTs) and observational and experimental studies are often inconsistent (24). Some RCTs have noted significant associations between vitamin D and a reduction in cancer occurrence (7,25), while others have not, with the latter being mainly attributed to poor study design and low supplementation dose given (26,27).

In experimental studies, vitamin D has been shown to regulate multiple cellular processes that can affect cancer development and progression (28,29), while risk reduction with better vitamin D status has been shown for multiple cancers in numerous epidemiological studies (7,30), as has improved survival in patients with cancer (31).

Our study adds important information to the sparse and conflicting evidence on the relationship between vitamin D and upper gastrointestinal cancer. In this study, we investigated the impact of ambient D-UVB dose, a key determinant of vitamin D status, on upper gastrointestinal risk. A fundamental benefit of using D-UVB over 25(OH)D measurement is that exposure over a prolonged period of time is captured. Limiting the exposure only to the wavelengths that induce vitamin D synthesis further supports the hypothesis that the mechanism by which UV may affect cancer development is via vitamin D synthesis and its effect on vitamin D status.

Our results are in agreement with the findings of Tran *et al.* who have found that higher lifetime UV radiation was associated with reduced odds of esophageal adenocarcinoma (13); however, we also observed some suggestive evidence of protective effect on SCC. Although the number of SCC cases was much smaller in both studies, we used a more specific exposure variable with greater spatial resolution, which potentially increased the power to detect associations in our study.

The study by Tran *et al.* was carried out in Australia, where UV radiation is dramatically higher than in the UK (32). Strikingly, the protective effect of ambient UVB was still observed in the current study, and it was stronger for higher annual D-UVB levels, suggesting a dose–response relationship. This was observed to a greater extent when split into annual D-UVB quintiles with a 34% reduction in esophageal cancer incidence for quintile 2, a 41% reduction for quintile 3, a 41% reduction for quintile 4 and finally a 48% reduction in cancer incidence in quintile 5. This suggests that risk reduction could be even greater than what is reported here in some instances, including in individuals who spend more time outdoors or in regions with greater UVB radiation. For comparison, mean yearly UVB in Greece is almost 2.5-fold higher compared to Ireland or the UK (33).

Although none have used as detailed and vitamin D–specific UVB measure, other studies that investigated UVB dose have also found a reduction in cancer incidence (34,35), and in addition to those, a large number of ecological studies are also in agreement with our study, reporting a strong inverse relationship between UV radiation and esophageal and gastric cancer risk (36–41). Interestingly, a recent monograph by the World Health Organization outlines evidence of an inverse relationship between UV radiation and breast, colorectal, prostate, ovarian cancers and Non-Hodgkin's lymphoma (42). This is the largest study to date examining the odds of developing esophageal and gastric cancer in relation to vitamin D–inducing UVB dose. Nesting our case–control study within a large cohort with extensive data on many aspects of lifestyle and health allowed us to assigning controls to cases at 5:1 ratio, conduct matching by important characteristics and adjust analysis for a range of potential confounders. Moreover, we had the information on vitamin D supplement use and oily fish consumption (the major dietary source of vitamin D) (43).

Furthermore, for this prospective study, cancer data used were gathered via linkage to cancer registries, and due to available information and large sample, we were able to examine different cancer types and subtypes independently, which is relevant due to the different underlying etiologies and presents a serious limitation of most previous studies. Annual ambient D-UVB dose was calculated for each participant individually based on their residential address, offering much greater special resolution to previous studies. This D-UVB measure has also been corrected for many important factors which can considerably alter the D-UVB dose reaching earth, such as cloud cover, ozone column and altitude. The strength of a similar D-UVB measurement has

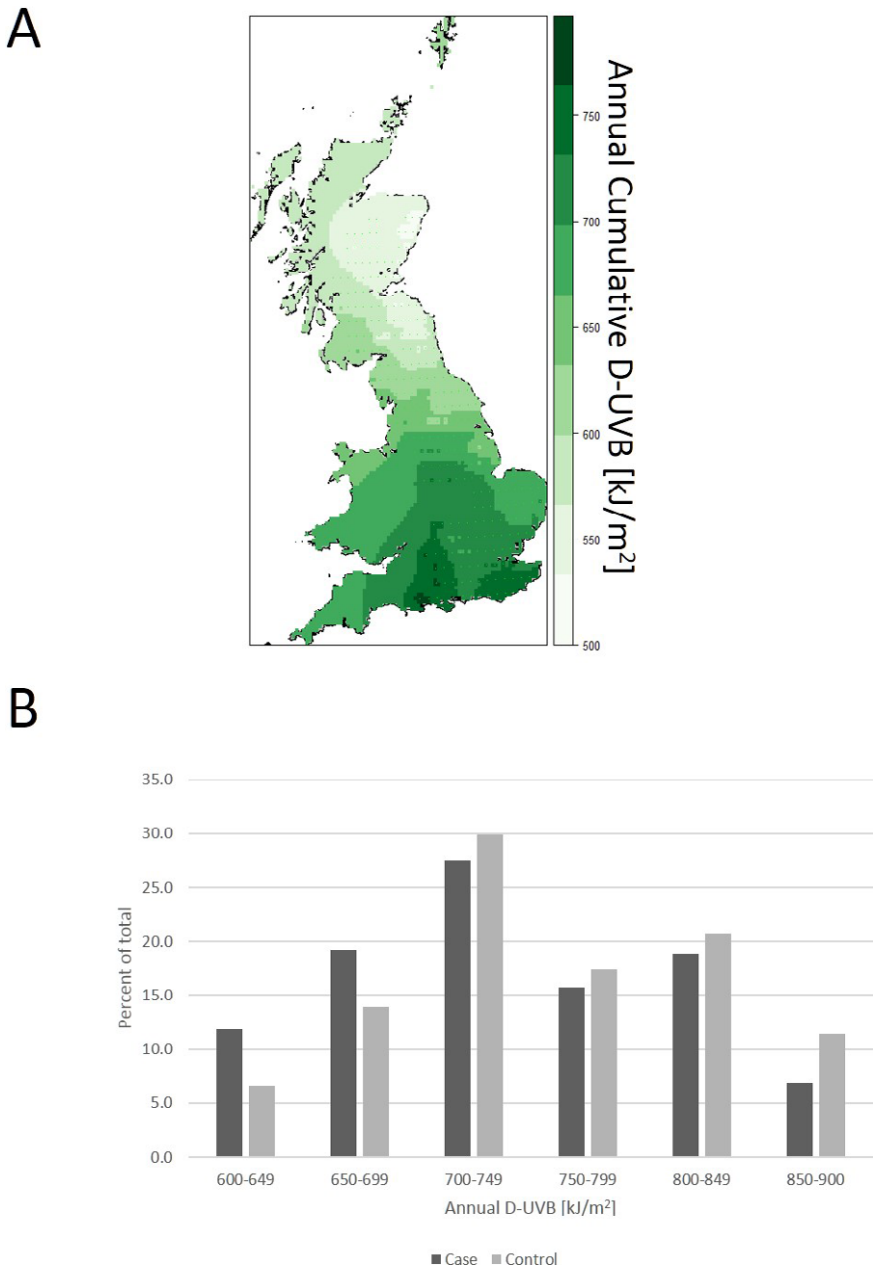

Figure 2. This figure shows A) the average cumulative annual D-UVB dose (kJ m^{-2}) over the UK from 2004 to 2017 from the Tropospheric Emissions Monitoring Internet Service (TEMIS) database. This was calculated by first finding the mean D-UVB dose per day from 2004 to 2017 in each grid. Each of the 365 daily D-UVB doses for each grid was then summed to give a cumulative dose for each of the 782 grids covering the UK. This was then mapped to the UK map to demonstrate a latitude gradient, B) a histogram of the distribution of annual D-UVB doses in both cases (n = 622) and controls (n = 3110).

been discussed in detail previously (15), and the D-UVB used in this paper is of even greater special and temporal resolution (22). Furthermore, this ambient UVB dose took into account annual D-UVB to get a "long-term average" UVB dose for each individual, rather than a seasonally biased estimate, which would have been the case if a point estimate of vitamin D, such as 25 (OH)D, was utilized. We excluded all individuals who had received a diagnosis of cancer, including skin cancer. Due to an established relationship between higher UV exposure and skin cancer (44,45), individuals who spend comparatively more time outdoors or sunbathing might have been selected out from our study. As a consequence, the upper gastrointestinal risk reduction may be even greater than what is reported here.

Data used in this study were precollected data; therefore, we did not have information about some factors of specific relevance to the research question: For example, Helicobacter pylori is an important risk factor for gastric cancer and adjustment for this could have impacted the results. We did not have information on "utilization" of ambient D-UVB for vitamin D production; however, exact information on this is virtually impossible to get for free-living subjects as it is determined by the length and timing of time spent outside, clothes and skin products warn, angle to

Table 2. Conditional logistic regression looking at the association between annual ambient D-UVB dose at a place of residence and esophageal and gastric cancer occurrence, overall and by cancer location.

Cases were matched to controls by age and sex in a 1:5 ratio. Each case was assigned a specific five controls so when stratified by cancer type/cancer location, the controls were stratified according to their specific case's cancer diagnosis. Unadj = unadjusted; Adj = adjusted; Es = esophageal; AC = adenocarcinoma; SCC = squamous cell carcinoma. Adjusted model was adjusted for smoking status, alcohol intake, BMI, highest qualifications, esophageal-gastric reflux and gastric ulcers. Significant associations are shown in Bold and those with suggestive significance are shown in italics.

Tertiles of ambient annual D-UVB at the place of residence were used to explore the relationship. Adjusted model has been adjusted for smoking status, BMI, alcohol consumption, esophageal–gastric reflux, highest qualifications and gastric ulcers, minus what was being stratified. Significant associations are shown in Bold and those with suggestive significance are shown in italics.

the sun, choice of sunny or shady spot, etc. Additionally, we did not have information on the duration individuals resided at the residence given; this is a limitation of this study as we calculated D-UVB dose based on their location of residence. We also unfortunately did not have 25(OH)D concentration, although strong relationship between D-UVB and 25(OH)D has been shown previously (15,44). While 25(OH)D is the best marker of vitamin D status at the time of blood draw, this provides little information about the average exposure over a prolonged period of time cancer takes to develop (45).

In conclusion, our study found that ambient vitamin D–synthesizing UVB radiation is inversely associated with the development of esophageal and gastric cancer, even in a high-latitude country with climatologically limited UVB radiation. Controlled exposure to sunlight, or vitamin D supplements, might be an economical and safe way to reduce upper gastrointestinal cancer incidence, but further research is needed.
